Abstract

In this project, we formulate an optimization problem to synthesize a tensegrity structure of desired shape and conduct preliminary experiments on micro-pipette aspiration of a red blood cell (RBC). In synthesis of tensegrity structures, we use the force density method. The reason for using the force density, defined as the force per unit length in the desired configuration, is twofold: (i) to directly impose constraints of positive and negative force densities in tension and compression elements in class 1 tensegrity where no two compression elements have a common vertex, by designating all members in the desired shape a priori as either a bar in compression or a cable in tension. We solve static equilibrium equations at the vertices in the desired configuration subject to constraints on force densities, which are the variables in the synthesis, respectively, and (ii) to obtain free lengths of all the members using the force densities. We use this method to synthesize a previously known semi-toroidal tensegrity arch with 24 bars and 102 cables and a hitherto unknown tensegrity of biconcave shape similar to that of a red blood cell comprising 24 bars and 112 cables. We also present static analysis of a tensegrity structure by minimizing the potential energy with unilateral constraints on the lengths of the cables, which cannot take compressive loads. We also extend the method to synthesize a tensegrity table of desired height and area with three bars and nine cables under a predefined load. The prototypes of all three synthesized tensegrities are made and tested.

Preliminary experiments are conducted to obtain static and viscoelastic force deflection responses of red blood cells (RBCs), so that a tensegrity model can be fit to those responses. For the experiment, the RBCs are isolated from the whole blood. The aspiration is carried out with a micro-pipette of diameter less than 2.5 μm (as the height and thickness of RBC is approximate 8 μm and 2.5 μm, respectively). It is observed that an RBC is aspirated at a single pressure step and thus making it difficult to obtain the needed force-deflection responses

.

Acknowledgment

I take this opportunity of acknowledging the people who have helped me directly or indirectly during my two years of stay in IISc and because of whom I am able to successfully complete the project.

Foremost, I would like to thank my Advisor, Prof. G. K. Ananthasuresh for his meticulous guidance, patience, and constant encouragement throughout the course of my work. I consider it a great honour to have worked with him and have been inspired by his sincerity and dedication towards work.

I would like to thank the examiners, Prof. C. S. Jog and Prof. Namrata Gundiah for their valuable suggestions and inputs during the course of my work.

I express my gratitude towards all faculty members of the department of Mechanical Engineering for the course work done with them. Their lectures have been very educative and inspiring. I would like to thank all the staff members of the department.

The M2D2, Multi-disciplinary and Multi-scale Devices and Design, Lab has always been conducive and friendly environment for technical discussions. I sincerely thank Santosh Bhargav, Suma, Shilpa, Srinath, Ramu and Bharat for their assistance in carrying out experimental work and fabrication of prototypes. I sincerely thank Rajesh at Health Center Lab, IISc, for providing me with blood samples for the experiments conducted.

Much I owe to my dear friends Snadeep, Subin, R. P. Singh and my lab-mates Jagdish, Puneet, Harish, Shantanu, Nandhini, Ramanath, Saurab, Nikhil, Gautam and Deepa with whom I worked, studied, learned, partied and enjoyed my stay at IISc. I got help whenever I asked them. Thank you all.

Words fail when it comes to acknowledging my family. Their constant, selfless love and encouragement made me what I am today.

I once again thank all the people who have made my stay at the Institute an enlightening one.

Chapter 1
Introduction

Multiple models are proposed for simulating the mechanics of a *cytoskeleton*, i.e., the interior framework of biological cells comprising actin filaments, intermediate filaments, and microtubules. They include: simple elastic, viscoelastic, or poro-viscoelastic continuum [1], porous gel [2], soft glassy material [3], bi-phasic model [4], and *tensegrity* (a portmanteau that combines *tens*ion and int*egrity*) [5] network model incorporating discrete structural elements that bear tension and compression. In this project, the cytoskeleton is modeled as a tensegrity structure.

Tensegrity structures are made of tension and compression elements [6]. The tension elements (cables) take tensile loads and compressive elements (bars) take compressive loads. Shown in Fig. 1(a) – (b) are the simplest tensegrity structures in 2D and 3D. Tensegrity structures use internal preload to assume a stiff and stable equilibrium shape under no external loads. Thus, Cytoskeleton models based on the concept of tensegrity are used to model the mechanical response of biological cells [7]. A cytoskeleton too has pre-stress in its members, whose role is to confer stable shape to the cell. Both cytoskeletons and tensegrity structures show "action-at-a-distance" phenomenon: an action at a point is carried forth to a faraway point despite the seemingly discrete network of elements. Tensegrity structures are stabilized by the continuous tension carried by the structural members. Their structural stiffness increases in proportion with the level of pre-stress present in them. Experimental observations show proportional relationship between the cell stiffness and that of the cytoskeleton [7]; controlled experiments in which selected portions of actin filaments were broken with a laser beam that led to the collapse of the cell. Thus, tensegrity modeling is tenable for simulating cytoskeletal mechanics. Tensegrity structures also have applications in deployable devices used for example, in space structures [8]. They are used in the field of architecture, where different types of tensegrity domes and arches are built [9]. As the large deformations in a tensegrity are controllable they find application in robotic arms [10]. There are different classes of tensegrity structures; class m tensegrity structures are structures where m bars share a single vertex [6]. We consider class 1 tensegrity structures with and without external loads.

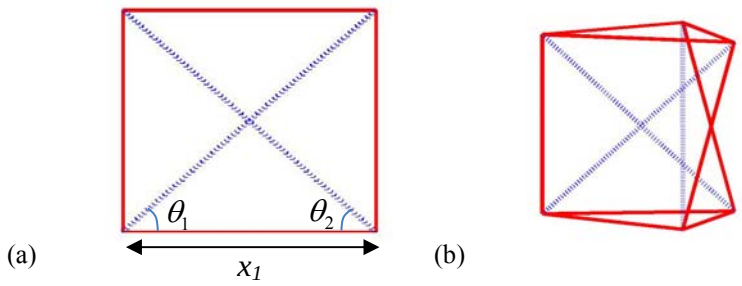

Fig.1. Simplest (a) 2D tensegrity structure known as tensegrity X and (b) 3D tensegrity known as ′3 bar prism′.

There are different methods to find the equilibrium state attained by a tensegrity structure for given connectivity and stiffness properties of the constituent bars and cables. These methods are generally known as *form-finding* methods [11]. They are classified into two categories: kinematic methods and static methods [6]. Some of the Kinematic methods of form-finding have analytical solutions [11]. Such methods are used for form-finding of prismatic tensegrities, where the cable lengths and the polygon face of the tensegrity prism are given, using which the lengths of the bars are calculated to get a stable tensegrity prism. Other Kinematic methods use nonlinear programming [12], by posing a constrained minimization problem, where connectivity and nodal points are known a priori and the lengths of the bars are maximized until a stable structure is obtained. The third Kinematic form-finding method uses dynamic relaxation [13] of different forms by varying the positions of the vertices of the system and solving the equilibrium equations at each node to find the unbalanced forces iteratively. The form is modified using the dynamic equations of motion. Although the kinematic methods have good convergence properties, they are only effective when the number of vertices in the structure is low.

Static methods of form-finding are of four types. In the force density method [14], for given connectivity of a tensegrity structure, the force density of each of the members is predefined. The nodal point coordinates are then calculated for the corresponding force densities that satisfy static equilibrium. In the analytical solution method [15], stable form of a rotationally symmetric tensegrity (e.g. a tensegrity prism) is found. Here, the nodal force balance is done to arrive at the angle subtended by the bars for given lengths of cables. In the energy method [16], the form of the tensegrity is found for which the total potential energy is minimum. Here the potential energy of both cables under tension and bars under compression are considered. In the reduced co-ordinate method [17], the bars are considered to be rigid and the equilibrium equations pertaining only to the cables are formulated with the help of the principle of virtual work.

In all the aforementioned methods the connectivity of the member elements and the stiffness property of the materials are given and we find the form that satisfies the equilibrium equations. It may be noted that form-finding addressed by these methods is a *forward problem* in the sense that the aim is to obtain a stable tensegrity form using given number of bars and cables and their connectivity and stiffness properties. The inverse problem is determining the geometry and force densities to obtain a prescribed shape. Form-finding of tensegrity structures with desired shape has been addressed by Masic [18], where the material stiffness properties and connectivity of the structure are known a priori. The difference between the coordinates of the vertices of the equilibrium form of the tensegrity and the coordinates of the prescribed vertices is minimized. The coordinates of the vertices and the force densities are the variables in this problem. Topology design of tensegrity design using mixed integer programming has been done by Ehara, S. and Kanno, Y. [19]. The formulation of the problem is given below:

$$
\begin{aligned}
\text{MIP1} \quad & \underset{\mathbf{q},\mathbf{x}}{Min} && -\textstyle\sum_{i\in N} x_i \\
& \textit{Subject to} && \mathbf{Hq} = 0 \\
& && -M\, x_i \le q_i \le M(1-x_i) - \varepsilon, && \forall i \in N_{bar} \\
& && \textstyle\sum_{i\in N(n_j)} x_i \le 1, && \forall j \in \mathbf{V} \\
& && x \in \{0,1\}^{|N|}.
\end{aligned}
$$

$$
\begin{aligned}
\text{MIP2} \quad & \underset{\mathbf{q},\mathbf{y}}{Min} && -\textstyle\sum_{i\in N_{cable}} y_i \\
& \textit{Subject to} && \mathbf{Hq} = 0 \\
& && q_i \le -\varepsilon, && \forall i \in N_{bar} \\
& && 0 \le q_i \le My_i, && \forall i \in N_{cable} \\
& && x \in \{0,1\}^{|N_{cable}|}.
\end{aligned}
\tag{1}
$$

Data $\mathbf{V}, M, \varepsilon$

where $\mathbf{V}$ is the set of all the vertices and M and ε are positive constants such that M is sufficiently large ($0 < \varepsilon << M$). It may be noted that $\mathbf{H}$ and $\mathbf{q}$ are the equilibrium matrix corresponding to the static equilibrium equations at the vertices and the force density vector respectively, and $\mathbf{x}$ and $\mathbf{y}$ are the vectors containing one or zero corresponding to the connections where bars and cables are present. Though the synthesis problem is solved, the structure we get is always statically indeterminate of order one or more.

The aforementioned are some of the few methods that address the inverse or the synthesis problem. In this project, we synthesize a tensegrity structure of desired shape, where the nodal points and connectivity are known a priori, and we find the stiffness properties of bars and cables of the tensegrity structure, which give the desired form for the tensegrity structure.

We synthesize a free-standing tensegrity structure (i.e., with no external loads) of desired shape by solving the force density method as an optimization problem with constraints on the force densities. We synthesize the tensegrity structures with external loads, which attain a predefined geometric constraint (e.g. height) under the application of the load, in two steps. The first step involves solving the force densities in an optimization problem to get the free-standing tensegrity. The second step involves static analysis, where we minimize the potential energy of the system under the externally applied loads with a reduced co-ordinate system. We use unilateral constraints on the cables in the form of sigmoid function to account for the slack condition of the cables under compressive loads. We check for the geometric constraint and update the tensegrity configuration and repeat the above steps until the geometric constraint is satisfied. We synthesize different desired shapes such as a semi-toroidal arch, biconcave tensegrity similar to the cytoskeleton of a red blood cell (RBC), and a table of desired height under the application of a prescribed external load.

Although we are representing the outer shape of RBC with tensegrity structures similar to that of a space-filling cytoskelton, the actual cytoskeleton of the RBC is a membrane skeletal network made of 2D protein polymer network (spectrin network) [20,21]. The membrane skeletal network of the RBC is made up of about 30000 junctional complexes [22]. Each junctional complex consists of a ~37 nm actin filaments (called protofilaments), six αβ spectrin heterodimers and six suspension complexes. The three pairs of αβ spectrin heterodimers spirally come down from the top of the protofilament and radiate outwards forming a hexagonal shape. These αβ spectrin heterodimers are attached to the lipid layer by a suspension complex, which are also made of proteins.

We have taken RBC for our study as it does not have a nucleus. The human RBCs do not have nucleus as it increases their oxygen carrying capacity. They generally act as vesicles carrying oxygen and carbon dioxide; so, they are not involved in cell division and growth and hence no need of a nucleus.

The mechanical properties of RBCs can be studied and measured experimentally by deforming them with a known force or stress and measuring the resulting deformation. Some of the widely used experimental techniques to study the mechanical properties of biological cells are atomic force microscope (AFM), the optical trap and micropipette aspiration (the experimental technique used in this project). Each of these experimental techniques has their own strengths and weaknesses. In AFM, the RBC surface is indented with a probe having constant velocity [23]. The probe being stiffer than the cell surface, the force produced in the AFM will be proportional to the indentation produced. The probe being stiffer small forces of the order 10-15 pN will be masked. In the optical trap, micron-sized refractile particles (like silica) are trapped in a laser beam focused through a high-numerical aperture microscope objective [24]. The trapped particle is touched to the surface of the RBC and the RBC is moved away from the adhered particle to get localized deformation of the cell membrane. The force is determined by the deflection of the particle in the trap perpendicular to the optical axis. This method has an advantage that no mechanical access to the cells is necessary. But optical traps do not give expected results when used to indent the RBC surface. In a micro-pipette aspiration experiment the cell membrane is pulled in the micro-pipette by controlled suction. One of the advantages of this experiment is that the cell can be either suspended in the solution or attached to a surface while the cell is bound to the micropipette and the negative pressure is applied. The micropipette aspiration can give measurements of three quantities: the cortical tension of the cell membrane; the cytoplasmic viscosity; and the cell elasticity [25]. In this project we try to aspirate the RBC.

The rest of the report is organized as follows. Chapter 2 contains the synthesis of tensegrity structures and the methodology followed in solving the problem. In chapter 3, the simulated examples with some of the fabricated tensegrity structures are shown. The micro-pipette aspiration experiment is discussed in chapter 4. Chapter 5 contains the summary and conclusions of the work.

Chapter 2
Towards Synthesis of Tensegrity Structures

For a free-standing tensegrity to be in static equilibrium, the net forces acting at each vertex should be zero. The internal and external forces in the member elements are resolved in the three directions and the sum of these resolved forces at each vertex is equated to zero to get the three equilibrium equations at each node. The equilibrium equations at vertex 1 in Fig. 2 can be written as:

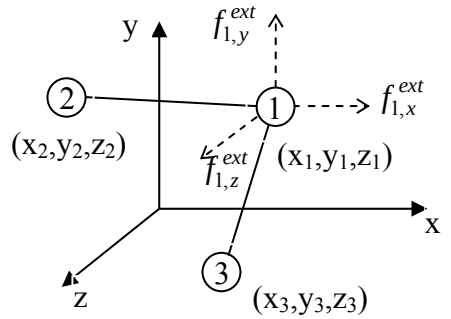

Fig.2: Equilibrium of vertex (node) 1in a tensegrity

$$\begin{aligned}
\frac{(x_1-x_2)f_{1-2}}{l_{1-2}}+\frac{(x_1-x_3)f_{1-3}}{l_{1-3}} &= f_{1,x}^{ext}\\
\frac{(y_1-y_2)f_{1-2}}{l_{1-2}}+\frac{(y_1-y_3)f_{1-3}}{l_{1-3}} &= f_{1,y}^{ext}\\
\frac{(z_1-z_2)f_{1-2}}{l_{1-2}}+\frac{(z_1-z_3)f_{1-3}}{l_{1-3}} &= f_{1,z}^{ext}
\end{aligned} \qquad (2)$$

where f_{i-j} and l_{i-j} are the internal force and length of an element connecting vertices i and j. For ease of calculation, we denote $\frac{f_{i-j}}{l_{i-j}}$ with q_{i-j}, where q_{i-j} is called the *force density*, i.e., force per unit length of the deformed element. Thus for the case where external loads are absent, we get:

$$\begin{aligned}
(x_1-x_2)q_{1-2}+(x_1-x_3)q_{1-3}&=0\\
(y_1-y_2)q_{1-2}+(y_1-y_3)q_{1-3}&=0\\
(z_1-z_2)q_{1-2}+(z_1-z_3)q_{1-3}&=0
\end{aligned} \qquad (3)$$

When there are n vertices, there will be $3n$ equations to be solved in m unknowns, m being the number of elements connecting n vertices. The number of elements in a tensegrity structure is selected by using Maxwell's rule [26], which states that the number of elements should be at least as many as $3n-6$ for a structure to be stiff. By Maxwell's rule it can be also seen that when $m>3n-6$, the structure will have $m-(3n-6)$ *states of self-stress*. Similarly when $m<3n-6$, the structure will have $(3n-6)-m$ *infinitesimal mode (mechanism).* A structure satisfying Maxwell's rule and having an infinitesimal mode also have a corresponding

state of self-stress or prestress. We choose m such that we have certain number of self-stress in our structure. As the tensegrity we are synthesizing are of class 1, no two bars will share a common vertex. Hence the number of bars in the structure will be $n/2$. The rest of the elements will constitute the cables of the structure.

The unknowns in Eq. (3) are the force densities $q_1, q_2, ..., q_m$. The resulting equations can be expressed in matrix form with the help of a connectivity matrix $\mathbf{C}$. Each row of matrix $\mathbf{C}$ represents the connectivity of the elements and each element in a particular row describes whether an element of the tensegrity structure is absent or an element begins or ends at that particular vertex. $\mathbf{C}$ is an $m \times n$ sparse matrix with m^{th} row having value 1 at the column corresponding to the vertex in which the member element emanates and -1 at the column corresponding to the node in which the element terminates with other elements of the row equal to zero. The sum of a row in matrix $\mathbf{C}$ should be zero. Thus we have:

$$\begin{aligned} \mathbf{C}^T diag(\mathbf{CX})\mathbf{q} &= 0 \\ \mathbf{C}^T diag(\mathbf{CY})\mathbf{q} &= 0 \\ \mathbf{C}^T diag(\mathbf{CZ})\mathbf{q} &= 0 \end{aligned} \tag{4}$$

where $\mathbf{X}, \mathbf{Y}$ and $\mathbf{Z}$ are $n \times 1$ vectors containing the x, y and z coordinates of the nodes respectively. $diag(\mathbf{CX})$ is an $m \times m$ diagonal matrix with vector $\mathbf{CX}$ constituting it's diagonal entries. Eq. (4) can be solved using singular value decomposition (SVD), but the resulting structure will be a tensegrity structure only for particular $\mathbf{C}$ matrices. In other cases although we may get solutions, it would merely result in trusses rather than a tensegrity structure. The tensegrity structure we solve for will be a linear combination of the solutions we get. Thus, we need to give constraints on the values of $\mathbf{q}$ so that the cables and bars have positive and negative values for $\mathbf{q}$ to ensure the tensegrity condition. So, we pose the problem as an optimization problem with constraints on the unknowns $\mathbf{q}$.

$$\begin{aligned} &\underset{\mathbf{q}}{Min} && (\mathbf{A} - \mathbf{f}^{ext})^2 \\ &where && \mathbf{A} = \begin{bmatrix} \mathbf{C}^T diag(\mathbf{CX})\mathbf{q} \\ \mathbf{C}^T diag(\mathbf{CY})\mathbf{q} \\ \mathbf{C}^T diag(\mathbf{CZ})\mathbf{q} \end{bmatrix}, \mathbf{f}^{ext} = \mathbf{0} \\ &Subject\ to && q_i < 0 && \forall i \in N_{bar} \\ & && -q_i < 0 && \forall i \in N_{cable} \\ &Data && \mathbf{C}, \mathbf{X}, \mathbf{Y}, \mathbf{Z}, \mathbf{f}^{ext}, N = N_{bars} \cup N_{cables} \end{aligned} \tag{5}$$

where N is the set of elements on the structure and N_{bar} is the set of elements that are bars and N_{cables} is the set of elements that are cables. After finding the force densities of each of the elements of the tensegrity structure we can find the free length of the individual elements for given cross-sectional area and Young's modulus of the material by fixing any two among the three of free length, cross-sectional area, and Young's modulus and finding the third one. We solve the minimization problem using the fmincon subroutine in MATLAB [27].

The second type of problem solved involves external forces. Here, we aim for the desired shape of the tensegrity under specified external load. The synthesis procedure for this is explained next.

Upon getting the desired structure, static analysis is done by minimization of potential energy approach. In static analysis of the tensegrity structure, we make following assumptions: (i) the bars are rigid and do not undergo any axial deformations or bending (ii) the strain energy of the cables and the work done by the external load contribute to the potential energy (iii) the cables can only take tensile load and become slack under compressive loads. We formulate the static problem as:

$$\begin{aligned} &\underset{g_i}{Min} \qquad PE = \sum_{k=1}^{n} \frac{1}{2S} K_k (L(g_i,l)_k - L_{0k})^2 - \sum_{m=1}^{r} F_m d(g_i,l)_m \\ &where \qquad S = 1 + e^{-sp\left(\frac{L(g_i)_k}{L_{0k}} - 1\right)} \\ &Data \qquad K, L_0, F, sp \end{aligned} \tag{6}$$

where K_i and L_{0i} are the stiffness and free lengths of cable in the tensegrity structure, l_i is the length of the bar, g_i is the generalized coordinate of the tensegrity structure in terms of the angles made by the bars with datum and final lengths of some cables. $L(g_i,l)$ and $d(g_i,l)$ are the final lengths of the cables and the displacements of the vertices at which the loads acts respectively. Both of them are functions of the generalized coordinates and the lengths of the bars. It may be noted that S is a sigmoid function used to account for the force-free slackness condition of the cables. The symbol sp is the steepness parameter of the sigmoid function.

The next step is to find the optimum height of a tensegrity structure which on application of a vertical load attains a desired shape. Equation (5) cannot be solved for all $\mathbf{f}^{ext} \neq 0$ (only a particular combination of the external load vector ($\mathbf{f}^{ext}$) can be solved) to get a tensegrity structure of desired shape. So, we pose the problem by imposing constraints on the force densities.

$$
\begin{aligned}
&\underset{a}{Min} && f = \left| h(a) - h^{*} \right| \\
&Subject\ to && \underset{q}{Min} && (\mathbf{A} - \mathbf{f}^{ext})^2 \\
& && Subject\ to && q_i < 0 && \forall i \in N_{bar} \\
& && && -q_i < 0 && \forall i \in N_{cable}
\end{aligned}
\tag{7}
$$

$$
\underset{x_i}{Min} \qquad PE = \sum_{k=1}^{n} \frac{1}{2S} K_k (L(x_i, l)_k - L_{0k})^2 - \sum_{m=1}^{r} F_m d(x_i, l)_m
$$

$$
where \quad S = 1 + e^{-sp\left(\frac{L(x_i)_k}{L_{0k}} - 1\right)}
$$

$$
Data \qquad \mathbf{C, X, Y, Z}, \mathbf{f}^{ext}, F, sp, N = N_{bars} \cup N_{cables}
$$

where K_i, L_{0i} and l_i are found from the output of Eq. (5) used in Eq. (7). h^{*} is the desired height the tensegrity structure should take under the application of load and a is the z coordinate of certain vertices of the initial free standing tensegrity. $h(a)$ is the height attained by the tensegrity structure which is a function of a. This is also an iterative process where the a changes until we get the required height.

Chapter 4
Results and Discussion

We use Eq. (5) to synthesize a previously known semi-toroidal tensegrity arch and an unknown tensegrity of biconcave shape of the cytoskeleton of a red blood cell. The semi-toroidal tensegrity arch (see Fig. 3) [28] is synthesized by first fixing the vertices according to the height and width of the arch. We take 48 vertices to make the outline of the arch. For a class 1 tensegrity there is no common vertex for two bars, leading to 24 bars. The connectivity is made such that three of the bars and nine cables form a unit tensegrity prism. With eight such prisms we can make the semi-toroidal tensegrity arch having 24 bars and 102 cables. We choose the cross-sectional areas of the bars and cables and the material (Young's modulus) used to fabricate them. Then, their free lengths can be solved using the force densities. We solve the optimization problem (Eq. (5)) to get the force densities and then use them to calculate the free lengths of the individual elements. The given data and results are indicated in Tables 1, 2 and 3. The assumed Young's modulus is 9 GPa and 35 GPa; and the area of cross-section is 3.85e-5 m^2 and 7.85e-7 m^2 for bars and cables respectively.

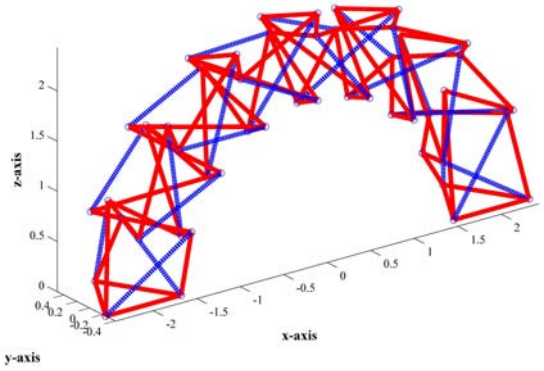

Fig. 3. A semi-toroidal tensegrity arch (blue dashed lines indicate the bars and the red lines indicate the cables).

Synthesis of the biconcave tensegrity (Fig. 5(a)) structure also involves the same steps as for the synthesis of the semi-toroidal arch. The nodal points are fixed on the surface generated by revolution of a Cassini's oval [29] corresponding to the size and shape of a red blood cell. The equation of a Cassini's oval is given by:

$$[(x-a)^2+y^2][(x+a)^2+y^2]=b^4$$
$$\text{where} \quad b=r_1 r_2$$
$$a=F_1+F_2 \tag{11}$$
$$\text{Diameter } d=2\sqrt{a^2+b^2}$$
$$\text{Thickness } t=\frac{b^2}{a}$$

where a and b are constants computed from the diameter and thickness data of a RBC. F_1 and F_2 are the two foci of the Cassini's oval and r_1 and r_2 are the distance between a point on the curve and the foci F_1 and F_2 respectively, ref. Fig. 4.

We approximate the biconcave shape with 48 nodal points. A single Cassini's oval is approximated with 12 points as shown Fig. 4. The whole RBC model is made using four Cassini's ovals. We synthesize the biconcave tensegrity from three eight bar tensegrity prisms. Thus, for a biconcave tensegrity we have 24 bars and 112 cables. Tables 4 and 5 contain the data given to the problem. Table 6 contains the computed force densities and free lengths by solving the optimization problem of Eq. (5). Fig. 5(b) shows the prototype made of using wooden pencils and hemp thread. By fitting a taut triangular plane that replaces two tensioned cables and a bar, we can visualize the shape better than with the cables and bars. Such a model is shown in Fig. 5(c).

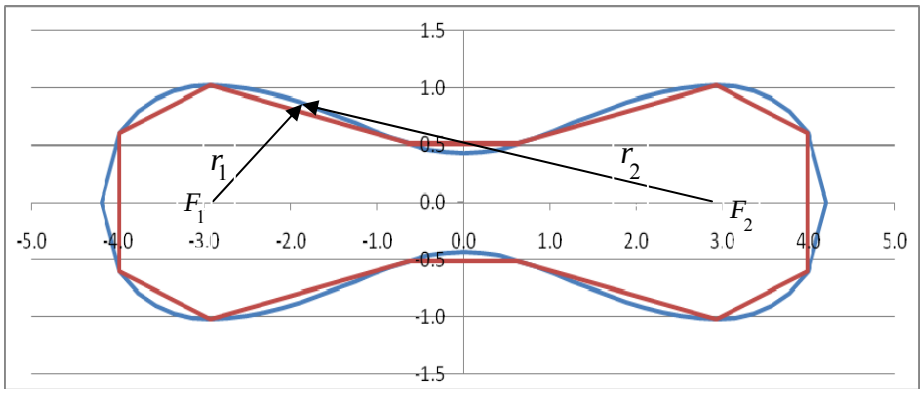

Fig. 4. A Cassini's oval modeled with diameter 8 μm and thickness 2 μm and the approximation curve made with 12 points.

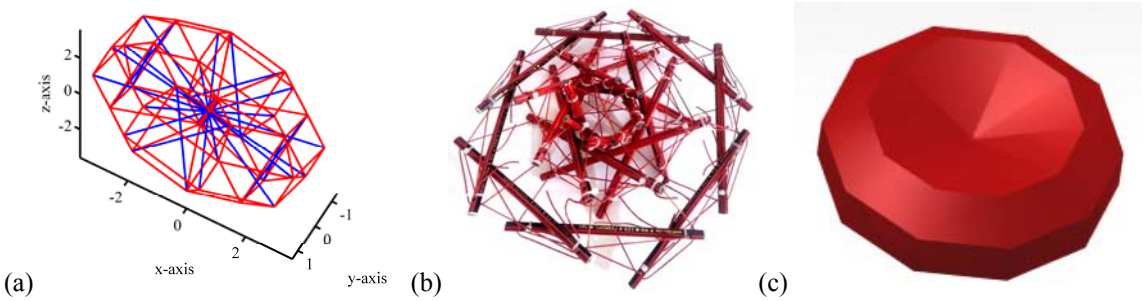

Fig. 5. (a) A biconcave tensegrity structure of a red blood cell (blue lines indicate the bars and the red lines indicate the cables). (b) A red blood cell prototype (scaled up) made with pencil and hemp threads. (c) Solid model of a red blood cell.

We also synthesized a tensegrity table that attains a desired height after application of load. The tensegrity table is made with three bars and nine cables and has six vertices. The vertices of the table are selected according to the area needed for the top of the table. The weight of a glass-top is the load. The heights (the z coordinates) of the first three vertices are selected to be as they rest on the ground (in x-y plane). The heights of the other three are randomly chosen for the initial analysis. The load on the table acts vertically down (i.e., in the $-z$ direction) at the three top vertices. The deformation of the table under load can be seen in the Figs. 6. (a) – (b). The table was synthesized such that the table has a height of 0.6 m for a load of 600 N. Tables 7 contains the coordinates of the vertices taken as an initial guess. Table 8 contains the connectivity data of the elements and the force densities and free lengths of the elements obtained after solving the optimization problem of Eq. (7).

Table 2. The connectivity of 96 elements that make the semi-torroidal tensegrity arch (last 24 elements (i.e. 103-126) are bars).

The designed tensegrity models are fabricated and tested. The semi-toroidal tensegrity arch and the biconcave tensegrity model of red blood cell are fabricated using wooden cylinders (pencil) and hemp thread (pencils act as bars and the hemp thread act as the cables). The tensegrity table is fabricated using aluminum rods for bars and braided stainless steel wire for cables. It is shown in Fig. 7(a-b). The table is stable and is currently used in our lab. As the weight of the glass top is nearly 40 kg, any small object (up-to a weight of 20 kg) placed on top of it does not disturb the stability of the structure.

Table 5. The connectivity of 136 elements to make the RBC biconcave model (last 24 elements (i.e. 113-136) are bars).

Chapter 4
Micropipette Aspiration of RBC

Aspiration of a cell into a glass micro-pipette using suction pressure is one of the techniques used to estimate the mechanical properties of cells. In this chapter we describe attempts made to aspirate RBCs, one of the smallest cells in the human body.

The first step involved in micro-pipette aspiration of RBC is to isolate them from the whole blood. Following steps are followed in the isolation of RBC from the whole blood received from the Health Center Lab, IISc:

1. To 400 µl of blood sample, 400 µl of histopaque-1077 (Sigma life science) is added and centrifuged at 2000 rpm for 10 min in the centrifuge (Hermle Inc.).
2. The supernatant is removed and 500 µl of saline is added to the pellet and centrifuged at 2000 rpm for 10 min. This step is repeated two more times.
3. 400 µl Percoll (Sigma life science) of density 1.1 g/ml (made from 1 ml percoll and 1.25 ml of 1.5 molar NaCl) is added to the remaining pellet and centrifuged at 2000 rpm for 10 min.
4. Once again the top layer is removed and 500 µl of saline is added to the pellets and centrifuged at 2000 rpm for 10 min. This step is repeated two more times.

Crenation (Fig. 8(b)) of RBC was observed when PBS (Phosphate Buffer Solution) was first used in place of saline. Crenation happens in RBCs when the solute concentration inside the cell is lower than that of the solute concentration in medium outside. The water in the cell diffuses out by osmosis and brings the solute concentration inside the cell equal to that of the outside medium. But, as the solution goes out, there is a reduction in the volume of the cytoplasm whereas the surface area of the cell remains constant. This prompts the cell surface to form abnormal notches.

Our setup for the micro-pipette aspiration consists of 3-degree-of-freedom (dof) XYZ micro-positioner (MP-285, Sutter Inc.), an inverted microscope (IX81, Olympus Inc.), a CCD (charged coupled device) camera (DP72, Olympus Inc.), a micro-injector (Xenoworks, Sutter Inc.), and a micro-pipette. All of these can be seen in Fig. 10. Pipettes are pulled using micro-pipette puller (Sutter Inc.) to get a bee-stinger micro-pipette. Bee-stinger micro-pipettes (Fig. 9 (a))are micro-pipettes having a shorter length and a sudden taper at the tip. They are useful in making micro-pipettes with smaller inner diameters with lesser drag during experiment when they are drawn through the solution due to their short height. Later, these micro-pipettes are forged to desired diameter using a micro-forge (Narshige Inc.). Once the pipettes are prepared, they are suitably positioned using the micro-positioner. The RBCs are aspirated under the inverted microscope. Fig 8(a) shows one such experiment in which the cell is drawn inside the pipette by applying a suitable suction pressure (in the order of hPa).

The suction force required to aspirate the cell into the pipette can be calculatred by:

$$F_0 = P(\pi R_p^2) \tag{8}$$

where F_0 is the suction force, P is the suction pressure and R_p is the inner radius of the micro-pipette. It is to be noted that the value of the force is assumed to be at a point but the actual pressure that the cell experiences is distributed in nature.

For a cell modeled as an elastic body, its Young's modulus E can be found out by [30]:

$$\Delta P = \frac{2\pi}{3} E \frac{L_p}{R_p} \phi \tag{9}$$

where ΔP is the pressure difference inside and outside the pipette, L_P is the length of the cell pulled into the pipette with radius R_P, and ϕ is a geometric constant with a value around 2.1 [30].

For liquid like flow of cells at pressures exceeding the cortical tension, the cyto-plasmic viscosity is calculated by [31]:

$$\eta = \frac{R_p \Delta P}{\left(\frac{dL_p}{dt}\right) m\left(1 - R_p/R\right)} \tag{10}$$

where η is the viscosity, R is the diameter of the cell outside the pipette, and m is a constant with a value around 9 [30].

The micro-pipette aspiration of RBC was conducted. Only 2 RBCs were aspirated and their values are given in table 9.

Table 9. Observations in micro-pipette aspiration of RBCs

cell	Pipette diameter (μm)	Pressure (hPa)
RBC	2.1	122
	2.1	155

Chapter 5
Summary and conclusions

In this report, we developed an optimization method to synthesize tensegrity structures of desired shapes. The coordinates of the vertices and the connectivity of the elements are the inputs to the problem, which we use to solve for the force densities in each of the member elements using the equilibrium equations at the vertices. Constraints are imposed on the force densities to accommodate tensions in bars and compressions in cables. The following conclusions can be drawn from the work presented here.

- The solution is unique for a given set of positions of the vertices and their connectivity with bars and cables. The free lengths of the elements change according to different materials assigned but the force densities do not change.
- Solving the constrained optimization problem posed for the purpose of synthesis of the tensegrity structure of desired shape is equivalent to constructing the null-space of the combined connectivity-coordinate matrix. When the rank of the null-space is more than unity, tensegrity structures can be constructed using linear combinations of the basis vectors of the null-space.

The micro-pipette aspiration of RBC was conducted, for which the RBCs were isolated from the whole blood. It is noticed that the RBCs are aspirated into the pipette at a single pressure step i.e., there is no separate base pressure and initiation pressure for RBCs. The force needed to aspirate a RBC is about 1.92e-10 N [32]. When the diameter of the pipette is more than 1.55 μm, the suction pressure becomes less than 100 Pa. The micro-injector (Xenoworks, Sutter Inc.) has minimum pressure increment 100 Pa, thus the difference in the initiation pressure and base pressure cannot be calculated. When the pipette diameter is smaller than 1.55 μm, the adequate suction pressure needed to start the aspiration is not built.
